27 **Abstract**

28 Ebola virus disease (EVD) is a complex zoonosis that is highly virulent in humans. The largest
29 recorded outbreak of EVD is ongoing in West Africa, outside of its previously reported and predicted
30 niche. We assembled location data on all recorded zoonotic transmission to humans and Ebola virus
31 infection in bats and primates (1976-2014). Using species distribution models these occurrence data
32 were paired with environmental covariates to predict a zoonotic transmission niche covering 22
33 countries across Central and West Africa. Vegetation, elevation, temperature, evapotranspiration and
34 suspected reservoir bat distributions define this relationship. At-risk areas are inhabited by 22 million
35 people, however the rarity of human outbreaks emphasises the very low probability of transmission to
36 humans. Increasing population sizes and international connectivity by air since the first detection of
37 EVD in 1976 suggest that the dynamics of human-to-human secondary transmission in contemporary
38 outbreaks will be very different to those of the past. [150/150]

39 **Introduction**

40 Ebola viruses have for the last forty years been responsible for a number of outbreaks of Ebola virus
41 disease (EVD) in humans (*Pattyn et al., 1977*), with high case fatality rates typically around 60-70%,
42 but potentially reaching as high as 90% (*Feldmann and Geisbert, 2011*). The most recent outbreak
43 began in Guinea in December 2013 (*Baize et al., 2014; Bausch and Schwarz, 2014*) and has
44 subsequently spread to Liberia, Sierra Leone and Nigeria (*ECDC, 2014*). The unprecedented size and
45 scale of this ongoing outbreak has the potential to destabilise already fragile economies and healthcare
46 systems (*Fauci, 2014*), and fears of international spread of a Category A Priority Pathogen (*NIH,*
47 *2014*) have made this a massive focus for international public health (*Chan, 2014*). This has led to the
48 current outbreak being declared a Public Health Emergency of International Concern on the 8th
49 August 2014 (*Briand et al., 2014; Gostin et al., 2014; WHO, 2014*).

50 The *Filoviridae*, of which *Ebolavirus* is a constituent genus, belong to the order *Mononegavirales*.
51 Two other genera complete the family: *Marburgvirus*, itself responsible for a number of outbreaks of
52 haemorrhagic fever across Africa (*Conrad et al., 1978; Gear et al., 1975; Smith et al., 1982; Towner*
53 *et al., 2006*) and *Cuevavirus*, recently isolated from bats in northern Spain (*Negredo et al., 2011*).
54 Five species of *Ebolavirus* have been isolated to date (*King et al., 2011; Kuhn et al., 2010*); the
55 earliest recognised outbreaks of EVD were reported in Zaire (now the Democratic Republic of the
56 Congo (DRC)) and Sudan in 1976 (*International Commission, 1978; WHO International Study Team,*
57 *1978*). The causative viruses were isolated (*Pattyn et al., 1977*) and later identified to be distinct
58 species, *Zaire ebolavirus* (EBOV) and *Sudan ebolavirus* (SUDV). A third species of *Ebolavirus*,
59 *Reston ebolavirus*, was isolated from *Cynomolgus* monkeys imported from the Philippines to a
60 facility in the United States, where they experienced severe haemorrhaging (*Jahrling et al., 1990*).
61 Whilst serological evidence of infection with this species has been reported in individuals in the
62 Philippines (*Miranda et al., 1991*), no pathogenicity has been reported beyond primates and porcids
63 (*Barrette et al., 2009; Feldmann and Geisbert, 2011*). In 1994 a fourth species, *Tai Forest ebolavirus*
64 was isolated from a veterinarian who had autopsied a chimpanzee in Côte d'Ivoire (*Le Guenno et al.,*
65 *1995*), though the virus has not been detected subsequently. The final species, *Bundibugyo ebolavirus*,
66 was responsible for an outbreak of EVD in Uganda in 2007 (*Towner et al., 2008*), as well as a more
67 recent outbreak in the DRC (*WHO, 2012*).

68 Initial analysis suggested that the viruses isolated from the current outbreak, originating in Guinea,
69 formed a separate clade within the five *Ebolavirus* species (*Baize et al., 2014*). Subsequent re-analysis
70 of the same sequences however, indicated that these isolates instead nest within the *Zaire ebolavirus*
71 lineage (*Dudas and Rambaut, 2014*), and diverged from Central Africa strains approximately ten
72 years ago (*Gire et al., 2014*).

73 Which reservoir species are responsible for maintaining Ebola transmission between outbreaks is not
74 well understood (*Peterson et al., 2004*), but over the last decade significant progress has been made in
75 narrowing down the list of likely hosts (*Peterson et al., 2007*) (Figure 1). Primates have long been
76 known to harbour filoviral infections, with the first Marburg strains identified in African green
77 monkeys in 1967 (*Beer et al., 1999; Siegert et al., 1967*). Significant mortality has also been reported
78 in wild primate populations across Africa, most notably in gorilla (*Gorilla gorilla*) and chimpanzee
79 (*Pan troglodytes*) populations (*Bermejo et al., 2006; Formenty et al., 1999; Rouquet et al., 2005*). The
80 high case fatality rates recorded in the great apes combined with their declining populations and
81 limited geographical range, indicate they are likely dead-end hosts for the virus and not reservoir
82 species (*Groseth et al., 2007*). A large survey of small mammals in and around Gabon identified three
83 species of bats which were infected with Ebola viruses – *Hypsignathus monstrosus*, *Epomops*
84 *franqueti* and *Myonycteris torquata* (*Leroy et al., 2005*). Subsequent serological surveys (*Hayman et*
85 *al., 2010; Pourrut et al., 2009*) and evidence linking the potential source of human outbreaks to bats
86 (*Leroy et al., 2009*) lend support to the hypothesis of a bat reservoir. This, coupled with repeated
87 detection of *Marburgvirus* in the fruit bat *Rousettus aegypticus* (*Towner et al., 2009*) and the only
88 isolations of *Cuevavirus* also from bats (specifically *Llovia virus* (*Negredo et al., 2011*)), all support
89 the suspicion that Chiroptera play an important role in the natural life-cycle of the filoviruses.

90 Humans represent a dead-end host for the virus, with only stuttering chains of transmission reported
91 between humans in the majority of previous outbreaks (*Chowell et al., 2004; Legrand et al., 2007*)
92 and no indication that humans can reintroduce the virus back into reservoir species (*Karesh et al.,*
93 *2012*). The incubation period in humans ranges from two days to three weeks, after which a variety of
94 clinical symptoms arise, affecting multiple organs of the body. At the peak of illness, haemorrhaging
95 shock and widespread tissue damage can occur and can eventually lead to death within 6-16 days
96 (*Feldmann and Geisbert, 2011*). Human-to-human transmission is mainly through direct unprotected
97 contact with infected individuals and cadavers, with infectious particles detected in a number of
98 different body fluids (*Feldmann and Geisbert, 2011*). The typical outbreak profile is defined by an
99 index individual that has recently come into contact with the blood of another mammal through either
100 hunting or the butchering of animal carcasses (*Pourrut et al., 2005*). Whilst it has been difficult to
101 identify the zoonotic source for the index cases of some outbreaks, a recurring theme of hunting and
102 handling bushmeat is suspected (Table 1) (*Boumandouki et al., 2005; Leroy et al., 2009; Nkoghe et*
103 *al., 2005; Nkoghe et al., 2011*). For some outbreaks, including the most recent, the initial source of
104 zoonotic transmission has not been identified. In subsequent human-to-human transmission, the
105 highest risk activities are those that bring humans into close contact with infected individuals. These
106 include medical settings where insufficient infection control precautions have been taken, as well as
107 home care and funeral preparations carried out by families or close friends (*Baron et al., 1983;*
108 *Boumandouki et al., 2005; Georges et al., 1999*). As the conditions required for transmission are

109 culturally and contextually dependent, opportunities for sustained transmission are highly
110 heterogeneously distributed. Typically, chains of infection do not exceed three or four sequential
111 transmission events, although occasionally (and particularly in the early stages of infection) a single
112 individual may be responsible for directly infecting a large number of others (*Brady et al., 2014*). In
113 the outbreak in Gabon in 1996, a single person was responsible for infecting ten other individuals
114 (*Milleliri et al., 2004*) whilst in the 1995 outbreak in the DRC, thirty five cases resulted from one
115 individual (*Khan et al., 1999*). Secondary transmission can be restricted by effective case detection
116 and isolation measures (*Shoemaker et al., 2012; WHO, 2014*). Where this cannot be achieved, either
117 due to a lack of infrastructure, poor understanding of the disease, or distrust of medical practices,
118 secondary cases can continue to occur (*Hewlett et al., 2005; Khan et al., 1999; Larkin, 2003*). As the
119 number of infections grows, the ability of healthcare systems to control the further spread diminishes
120 and the risk of a large outbreak increases.

121 The recent outbreak in Guinea and surrounding countries indicate that the previous paradigm for
122 Ebola outbreaks is shifting (*Briand et al., 2014; Chan, 2014*). The last forty years of EVD outbreaks
123 were accompanied by considerable changes in demographic patterns throughout Africa. There has
124 been a large increase in population size coupled with increasing urbanisation (*Cohen, 2004; Linard et*
125 *al., 2013; Seto et al., 2012*). African populations have also become better connected internally and
126 internationally (*Huang and Tatem, 2013; Linard et al., 2012*). Only recently have we begun to
127 understand the dynamic nature of these travel patterns (*Garcia et al., 2014; Gonzalez et al., 2008;*
128 *Simini et al., 2012; Wesolowski et al., 2013; Wesolowski et al., 2012*) which have been clearly
129 demonstrated to influence disease transmission over different temporal and spatial scales (*Brockmann*
130 *and Helbing, 2013; Hufnagel et al., 2004; Pindolia et al., 2014; Stoddard et al., 2009; Talbi et al.,*
131 *2010; Yang et al., 2008*). Changes in land use and penetration into previously remote areas of
132 rainforest bring humans into contact with potential new reservoirs (*Daszak, 2000*), while changes in
133 human mobility and connectivity will likely have profound impacts on the dispersion of Ebola cases
134 during outbreaks. These conditions are thought to have a major role in setting the stage for the current
135 outbreak.

136 This paper aims to define the areas suitable for zoonotic transmission of *Ebolavirus* (*i.e.* those routes
137 defined in Figure 1 excluding human-to-human transmission) through species distribution modelling
138 techniques. The fundamental niche of a species can be conceptualised as the confluence of
139 environmental conditions that support its presence in a particular location (*Franklin, 2009*). Species
140 distribution models quantitatively describe this niche based on known occurrence records of the
141 organism and their associated environmental conditions, enabling predictions of the likely geographic
142 distribution of the species in other regions (*Elith and Leathwick, 2009*). The era of satellites and
143 geographical information systems has made high resolution global data on environmental conditions
144 increasingly available (*Hay et al., 2006; Weiss et al., 2014*). Species distribution modelling using

145 flexible machine learning approaches have been successfully applied to map the global distributions
146 of disease vectors (*Sinka et al., 2012*) and pathogens such as dengue (*Bhatt et al., 2013*), influenza
147 (*Gilbert et al., 2014*) and leishmaniasis (*Pigott et al., 2014*).

148 Previous studies applied the GARP (Genetic Algorithm for Rule-set Production) species distribution
149 modelling approach (*Stockwell and Peters, 1999*) to the locations of twelve Ebola outbreaks in
150 humans between 1976 and 2002 to map the likely distribution of Ebola viruses (*Peterson et al., 2004*)
151 and as a mechanism to identify potential reservoir hosts (*Peterson et al., 2004; Peterson et al., 2007*).
152 Here we update and improve the maps of the zoonotic transmission niche of EVD by: (i)
153 incorporating more recent outbreak data from outside the formerly predicted niche of EVD; (ii)
154 integrating for the first time data on outbreaks in primates and the occurrence of the virus in the
155 suspected Old World fruit bat (OWFB) reservoirs; (iii) using new satellite-derived information on
156 bespoke environmental covariates from Africa, including new distribution maps of the OWFB; and
157 (iv) using new increasingly flexible niche mapping techniques in the modelling framework. To
158 elucidate the relevance of these maps for transmission, we have also calculated the population at risk
159 of primary spillover outbreaks from the zoonotic niche of EVD in Africa, and we investigated the
160 changing nature of the populations within this niche.

161

162 **Results**

163 Reported EVD outbreaks

164 In total, 23 outbreaks of Ebola virus were identified in humans across Africa, consisting of a
165 hypothesised 30 independent primary infection events (Table 1 and Figure 2). These outbreaks span
166 the last forty years from the first outbreaks in 1976 to the five outbreaks that have occurred since 2010
167 (Table 1). The locations of the index cases span from West Africa, with the most westerly outbreak
168 ongoing in Guinea, to Gabon, the Republic of Congo (ROC), the DRC, South Sudan and Uganda.
169 Before December 2013, a total of 2,322 cases had occurred from *Ebolavirus* infections, a number
170 already overtaken by the likely underreported current case count of the ongoing outbreak >2,250
171 (*WHO, 2014*)(Figure 2A). Of the four viruses circulating in Africa, *Zaire ebolavirus* has been
172 responsible for the most outbreaks (13), followed by *Sudan ebolavirus* (7) and *Bundigbuyo ebolavirus*
173 with just two outbreaks in 2007/8 and 2012. Tai Forest has caused one confirmed infection in humans,
174 from which the patient recovered (*Formenty et al., 1999; Le Guenno et al., 1995*). Although outbreaks
175 have been reported since 1976, there was an absence of reported outbreaks in humans for 15 years
176 between 1979 and 1994 (although antibodies in humans were identified over the period (*Kuhn, 2008*))
177 and the frequency of outbreaks has increased substantially post 2000 (Figure 2A).

178 Reported Ebola virus infections in animals

179 A total of 51 surveyed locations reporting infections in animals were identified in the literature since
180 the discovery of the disease (Table 2 and Figure 3). These comprised 17 infections in gorillas (*Gorilla*
181 *gorilla*), nine infections in chimpanzees (*Pan troglodytes*), 18 in OWFB and two in duikers
182 (*Cephalophus* spp.). A large proportion of the great ape cases originated from the ROC / Gabon
183 border, coinciding with the main known distributions of both chimpanzees and gorillas (*Petter and*
184 *Desbordes, 2013*) and representing a period of well-documented great ape Ebola outbreaks in and
185 around the Lossi Animal Sanctuary (*Bermejo et al., 2006; Rouquet et al., 2005; Walsh et al., 2009*).
186 All animal isolations of Ebola viruses have come from countries that have also reported index cases of
187 human outbreaks, with the exception of several seropositive bats from a survey in southern Ghana.

188 Predicted distribution of suspected reservoir species of bats.

189 Three species of bats, *Hypsignathus monstrosus*, *Myonycteris torquata* and *Epomops franqueti*, were
190 identified as the most likely candidates to be reservoir species for Ebola viruses due to high
191 seroprevalence and the isolation of RNA closely related to *Zaire ebolavirus* (*Leroy et al., 2005; Olival*
192 *and Hayman, 2014*). In total, 239 locations were identified from the Global Biodiversity Information
193 Facility (GBIF) (*GBIF, 2014*): 67 for *H. monstrosus* (Figure 4A), 52 for *M. torquata* (Figure 4B) and
194 120 for *E. franqueti* (Figure 4C). Distribution models for all three species demonstrated predictive

195 skill (indicated by an area under the curve (AUC) greater than 0.5) as follows: *H. monstrosus* AUC
196 0.63±0.04; *M. torquata* AUC=0.59±0.04; *E. franqueti* AUC=0.58±0.03, n=50 submodels for all three
197 species. In addition, each species was broadly predicted within its considered expert opinion range
198 (Figure 4A-C) (Schipper *et al.*, 2008). The marginal effect plots (not shown) were strongly influenced
199 by land surface temperature (LST) and vegetation (as measured by the enhanced vegetation index
200 (EVI)). The predicted combined distribution of these species (Figure 4D), covers West and Central
201 Africa, specifically the moist forests of the northeastern, western and central Congo basin, and
202 Guinea, as well as the Congolian coastal forest ecoregions (WWF, 2014).

203 Predicted environmental suitability for zoonotic transmission of Ebola

204 The predicted environmental niche for zoonotic transmission of EVD is shown in Figure 5. All
205 countries with observed index cases of EVD (n=7, hereafter Set 1) have areas of the highest
206 environmental suitability (see list in Table 1). In addition, areas of high environmental suitability for
207 zoonotic transmission are predicted in a further 15 countries where, to date, index cases of the four
208 African species of *Ebolavirus* have not been recorded. These are Nigeria, Cameroon, Central African
209 Republic (CAR), Ghana, Liberia, Sierra Leone, Angola, Tanzania, Togo, Ethiopia, Mozambique,
210 Burundi, Equatorial Guinea, Madagascar and Malawi (hereafter Set 2).

211 The AUC for the Ebola model was relatively high (AUC=0.85±0.04, n=500 submodels) indicating
212 that the model could strongly distinguish regions of environmental suitability for EVD. Enhanced
213 vegetation index had the greatest impact on the distribution (relative contribution (RC) of 65.3%)
214 followed by elevation (RC=11.7%), night-time land surface temperature (LST) (RC=7.7%), potential
215 evapotranspiration (PET) (RC=5.7%) and combined bat distribution (RC=3.8%). Marginal effect
216 plots are presented in Figure 5 – figure supplement 2.

217 In total, 22.2 million people are predicted to live in areas suitable for zoonotic transmission of Ebola.
218 The vast majority, 21.7 million (approximately 97%), live in rural areas, as opposed to urban or peri-
219 urban areas (CIESIN/IFPRI/WB/CIAT, 2007; WorldPop, 2014). Of these, 15.2 million are in Set 1 and
220 7 million are in Set 2. In terms of ranked populations at risk, DRC, Guinea and Uganda are highest in
221 Set 1 and Nigeria, Cameroon and CAR are top in Set 2. For a full listing of these populations living in
222 areas of risk, see the stacked bar plot in Figure 5B.

223 National level demographic and mobility changes

224 Over the 40 year period since discovery of EVD, the total population living in those countries
225 predicted to be within the zoonotic niche has nearly tripled (from 230 million to 639 million) and the
226 proportion of the population in these countries living in an urban (rather than rural) setting has
227 changed from 25.5% to 59.2% (Figure 6).

228 Data on the connectivity of human populations over this period were not available. We can infer
229 however, intuitively, empirically and theoretically (*Simini et al., 2012; Zipf, 1946*) that rates of
230 population movement within a country will scale directly in proportion to population growth.

231 International connectivity by airline traffic

232 Records of passenger seat capacity are available since 2000 and show substantive increases over the
233 period in Set 1 (from 2.96 to 4.77 million, a fractional change of 1.61) and Set 2 (from 5.6 to 15.6
234 million, a change of 2.8) (Figure 7A). More specific data on passenger volumes show almost
235 universally similar increases since 2005 with Set 1 nations changing from 2 million to 2.5 million, a
236 fractional change of 1.22 and Set 2 changing from 5 million to 7.9 million, a change of 1.57 (Figure
237 7B).

238 Global analysis of airline passenger volumes demonstrates that international connectivity has
239 increased amongst all global regions and national income strata (Figure 8). Total passenger volumes
240 have increased by a third from 9.5 to over 14 million during the eight year window (2005-2012)
241 where records are available. The largest increases have occurred in WHO regions (*WHO, 2014*)
242 outside of the sub-Saharan African region (AFRO) (Figures 8A and B). In 2012, almost half of the
243 final destinations of those travelling from these at-risk countries were to other AFRO nations (47%).
244 Other frequent destinations were in Europe (EURO; 27%) and the Eastern Mediterranean (EMRO;
245 13%). Similarly, analysis of passenger volumes by World Bank national income groupings (*WHO,*
246 *2014*) (Figures 8C and D) show that in 2012 40% of all passenger final destinations were to low or
247 low-middle income countries.

248

249 **Discussion**

250 Summary of the main findings

251 We have re-evaluated the zoonotic niche for EVD in Africa. In doing so we have (i) used all existing
252 outbreaks to assemble an inventory of index cases (n=30); (ii) added to this all confirmed records of
253 Ebola virus in animals (n=51); (iii) assembled more accurate and contemporary environmental
254 covariates including new maps of the distribution of confirmed OWFB reservoirs of the disease; and
255 (iv) used the latest niche modelling techniques to predict the geographic distribution of potential
256 zoonotic transmission of the disease. Using these predictions we have estimated the populations at
257 risk of EVD both in countries which have confirmed index cases (Set 1, n=7) and those for which we
258 predict strong environmental suitability for outbreaks (Set 2, n=15). In all countries at risk we show
259 that since the discovery of EVD in 1976, urban and rural populations have increased and have become
260 more interconnected both within and across national borders. During the last 40 years the increasing
261 size and connectivity of these populations may have facilitated the subsequent spread of EVD
262 outbreaks. These factors underline a change in the way in which EVD interacts with human
263 populations.

264 Interpreting the zoonotic niche

265 The remote and isolated nature of Ebola zoonotic transmission events, paired with the relatively poor
266 diagnostics and understanding of the disease transmission routes in early outbreaks, mean that under-
267 reporting of previous outbreaks is probable. An increasing understanding and description of a broader
268 range of symptoms used in case definitions of EVD (*Feldmann and Geisbert, 2011; Leroy et al.,*
269 *2000*) also increase the possibility that past outbreaks may have been misattributed to different
270 diseases (*Tignor et al., 1993*). This poor detectability of EVD also clearly limits capacity to accurately
271 identify the locations and transmission routes of index cases (*Baize et al., 2014; Heymann et al.,*
272 *1980*). We must assume, as has been done previously (*Jones et al., 2008; Peterson et al., 2004*), that
273 the first reported cases are representative of the true location of the index cases. Where possible we
274 have represented this geographic uncertainty by attributing the index case to a wide-area polygon
275 which then incorporated this uncertainty into the mapping process (see Methods).

276 The relationship between the EVD niche and the environmental covariates (Figure 5 – figure
277 supplement 2), particularly the high relative contribution of the vegetation index, underscore that there
278 are clear environmental limits to transmission of the virus from animals to humans, and that
279 ecoregions dominated by rainforest are the primary home of such zoonotic cycles. Our analysis has
280 shown that the zoonotic niche of the pathogen is more widespread than previously predicted or
281 appreciated (*Peterson et al., 2004*), most notably in West Africa.

282 This analysis used information from all human outbreaks and animal infections to delineate the likely
283 zoonotic niche of the disease. Further analysis, excluding the existing outbreak focussed in Guinea
284 from the dataset used to train the model (Figure 5 – figure supplement 3), still resulted in prediction of
285 high suitability in this region, with the presumed index village located within 5km of an at-risk pixel.
286 This implies that the eco-epidemiological situation in Guinea is very similar to that in past outbreaks,
287 mirroring phylogenetic similarity in the causative viruses (*Dudas and Rambaut, 2014; Gire et al.,*
288 *2014*). The ecological similarity between the past and current outbreaks also lends support to the
289 notion that the scale of this outbreak is more heavily influenced by patterns of human-to-human
290 transmission than any expansion of the zoonotic niche.

291 Interpreting Population at Risk

292 It is important to appreciate that this zoonotic niche map delineates areas in which populations are at
293 risk of zoonotic transmission of EVD (Figure 5B). It does not predict the likelihood of EVD spillover,
294 the likelihood of an outbreak establishing, or its subsequent rate of spread within a population.
295 Increasing human encroachment and certain cultural practices sometimes linked with poverty, such as
296 bushmeat hunting, result in increasing exposure of humans to animals which may harbour diseases
297 including Ebola (*Daszak, 2000; Wolfe et al., 2005; Wolfe et al., 2007*). Increasing human population
298 may accelerate the degree of risk through these processes but spatially refined information on these
299 factors is not available comprehensively. It is hoped that as the understanding of the risk factors for
300 zoonotic transmission of *Ebolavirus* to humans increases, it will be possible to incorporate this
301 information into future risk mapping assessments.

302 Previous considerations of the geographic distribution of EVD have used human outbreaks alone. We
303 have updated this work to include the last decade of outbreaks, as well as disaggregated outbreaks
304 where evidence suggests multiple independent zoonotic transmission events overlap in space and
305 time. Furthermore, our modelling process accommodates uncertainty in geopositioning of these index
306 cases by utilising both point and polygon data. In addition, we include occurrence of infection in
307 wildlife, important to the wider scale of zoonotic transmission (Figure1), which in total has increased
308 the dataset used in the model to 81 occurrences. The rareness of EVD outbreaks and the prevalence of
309 detectable Ebola virus in reservoir species suggests that there will always be a limited set of
310 observation data when compared to mapping of more prevalent zoonoses (*Pigott et al., 2014*). The
311 results demonstrate predictive skill using a stringent validation procedure, however, indicating strong
312 model performance even with this relatively limited observation dataset.

313 A broad zoonotic niche is predicted across 22 countries in Central and West Africa. Whilst several of
314 these countries have reported index cases of EVD, others have not, although serological evidence in
315 some regions points to possible underreporting of small-scale outbreaks (*Kuhn, 2008*). With improved

316 ecological understanding, particularly with improvements to our knowledge of specific reservoir
317 species and their distributions, it may be possible to delineate areas not at risk due to the absence of
318 these species.

319 Despite relatively a large population living in areas of risk and the widespread practice of bushmeat
320 hunting in these predicted areas (*Brashares et al., 2011; Kamins et al., 2011; Mfunda and Røskoft,*
321 *2010; Wolfe et al., 2005*), *Ebolavirus* is rare both in suspected animal reservoirs (*Leroy et al., 2005;*
322 *Olival and Hayman, 2014*) and in terms of human outbreaks (Table 1). There is some indication
323 however, that the frequency of Ebola outbreaks has increased since 2000, as shown in Figure 2A. We
324 have shown that the human population living within this niche is larger, more mobile and better
325 internationally connected than when the pathogen was first observed. As a result, when spillover
326 events do occur, the likelihood of continued spread amongst the human population is greater,
327 particularly in areas with poor healthcare infrastructure (*Briand et al., 2014; Fauci, 2014*).

328 Whilst rare in comparison to other high burden diseases prevalent in this region, such as malaria
329 (*Gething et al., 2011; Murray et al., 2012*), Ebola outbreaks can have a considerable economic and
330 political impact, and the subsequent destabilisation of basic health care provisioning in affected
331 regions increases the toll of unrecorded morbidity and mortality of more common infectious diseases
332 (*Murray et al., 2014; Wang et al., 2014*), throughout and after the epidemic period. The number of
333 concurrent infections during the present outbreak represents a significant strain on healthcare systems
334 that are already poorly provisioned (*Briand et al., 2014; Chan, 2014; Fauci, 2014*) and many other
335 Set 1 and Set 2 countries rank amongst the lowest per capita healthcare spenders. These
336 considerations should be paramount when international organizations debate the financing
337 requirements for the improvement of healthcare needed in the region and the urgency with which new
338 therapeutics and vaccines can be brought into production (*Brady et al., 2014; Goodman, 2014*).

339 Together, these considerations necessitate prioritisation of efforts to reinforce and improve existing
340 surveillance and control, and encourage the development of therapeutics and vaccines. The national
341 population at risk estimates presented here would be a strong rationale for improving, prioritising and
342 stratifying surveillance for EVD outbreaks and diagnostic capacity in these countries. We believe it
343 would be prudent to test OWFB species in Set 2 countries for Ebola virus (*Hayman et al., 2012*),
344 particularly during the bat breeding season to maximise chances of isolation in order to clarify the
345 outbreak risk in these countries. In all Set 1 and Set 2 countries, raising awareness about the risk
346 presented by reservoir bats and incidental primate hosts and the modes of transmission of this disease
347 could be of value. Finally, increasing our capacity to rapidly map ever changing biological threats is
348 also a core need (*Hay et al., 2013*).

349 Interpreting International Connectivity

350 The increasing connectedness of the Africa region means that EVD is now a problem of international
351 concern. While most EVD secondary transmission occurs locally and is likely transported *via* ground
352 transit (*Francesconi et al., 2003*), the potential for international spread of infection is possible, as
353 demonstrated by the importation of the disease from Liberia to Nigeria, culminating in further
354 secondary transmission in Lagos (*WHO, 2014*). The aetiology of EVD infection and disease
355 progression means that an international outbreak propagated by air travel remains unlikely,
356 particularly in high-income countries better able to handle EVD cases (*Fauci, 2014*). Nevertheless, a
357 non-negligible threat remains, particularly in the low and middle income destinations and the rapid
358 increase in global connectivity of these at-risk regions indicates that international airports could see
359 more imported cases (*Chan, 2014*).

360 Future work

361 We have focussed on reanalysing the zoonotic niche for EVD transmission and the characterisation of
362 the populations at risk to improve the landscape in which future risk and impact of EVD outbreaks
363 can be discussed. During the current emergency much of the work will concentrate on routes of
364 secondary transmission in the human population – conceptually the red arrow of the H box in Figure
365 1. An important task is to stratify the risk of EVD spread both within and between countries and
366 identify the most likely pathways of spread for characterisation and surveillance. Our next priority
367 therefore is to investigate aspects of secondary human-to-human transmission by documenting the
368 rate of geographic spread of EVD during the past and ongoing epidemics to help understand changes
369 in these patterns in the historical record. Simulating these movements in a real landscape of
370 population movement patterns, inferred from population movements assessed by mobile phones and
371 other data (*Garcia et al., 2014*), as well as parametric movement models (*Simini et al., 2013*) is a
372 logical next step, and can be used in future targeting of interventions and potential new treatments for
373 both the current and future outbreaks (*Brady et al., 2014; Goodman, 2014*).

374 As previously discussed, whilst there is the risk of human travel during the latent phase of infection,
375 and therefore potential for international spread, the high pathogenicity during infectiousness
376 (immobilising infected persons) and the likely rapid and effective isolation measures implemented in
377 regions with strong health care systems, limit the pandemic potential of EVD. Nevertheless,
378 improvement of international containment plans and informed discussions of potential risks to airline
379 carriers and populations of other regions will be supported by knowledge of local, regional and
380 international population flows. Assessing these flows by air traffic volumes is an ongoing priority.

381 There are several other zoonotic viral haemorrhagic fevers (for example *Marburgvirus*, Lassa fever,
382 hantaviral infections and arenaviruses) that are of similar public health and biosecurity concern
383 (*Bannister, 2010*), due to their high virulence and mortality and their potential to cause outbreaks and

384 spread internationally. Despite this their geographical distributions are poorly understood (*Hay et al.*,
385 2013). Many of the methods applied here can be adapted to these diseases and improve our
386 geographical understanding of the risk presented by these pathogens.

387 We are in the midst of a public health emergency that will likely last for many more months (*Chan*,
388 2014) and which has brought EVD to global attention. We emphasise that the maps of zoonotic
389 transmission presented here do not enable assessment of secondary transmission rates in human
390 populations, but they do act as an evidenced-based indicator of locations with potential for future
391 zoonotic transmission and thus outbreaks. Interestingly, early reports of another independent zoonotic
392 outbreak in the DRC (*MSF, 2014*) are in predicted at-risk areas. An improved understanding of the
393 spatial extent of the zoonotic niche can only help future efforts in biosurveillance.

394

395 **Methods**

396 Methodological overview

397 A boosted regression tree (BRT) modelling framework was used to generate predictive risk maps of
398 the zoonotic Ebola virus niche in Africa. This methodology combines regression trees, where trees are
399 built according to optimal decision rules based on how binary decisions best accommodate a given
400 dataset (*De'ath, 2007; Elith et al., 2008*), and boosting, which selects the tree that minimises the loss
401 function. In doing so, a parameter space is defined which captures the greatest amount of variation
402 present in the dataset. In order to train the model, four component datasets were compiled: (i) a
403 comprehensive dataset of the reported locations of Ebola virus transmission from a zoonotic reservoir
404 to a human; (ii) a dataset of the locations of Ebola virus infections in suspected reservoir and (non-
405 human) susceptible host species (iii) a suite of ecologically relevant environmental covariates for
406 Africa, including predicted distribution maps of suspected reservoir bat species and (iv) background
407 (or pseudo-absence) records representing locations where zoonotic Ebola virus has not been reported.
408 This study was limited to the African continent since no natural outbreaks of EVD have occurred
409 outside the continent (*CDC, 2014*). Only *Reston ebolavirus* has a distribution reported outside of
410 Africa, focussed in the Philippines, but has never been reported as pathogenic in humans; as a result
411 this species was not included in the analysis.

412 Identifying index cases and reconstructing zoonotic transmission events in space and time

413 Tables detailing proven outbreaks of Ebola virus, initially sourced from the scientific literature (*Kuhn,*
414 *2008*) and from health reporting organisations (*CDC, 2014*), were used to coordinate searches of the
415 formal scientific literature using Web of Science and PubMed for each specific outbreak. Relevant
416 papers were abstracted and where possible outbreak-specific epidemiological surveys were sourced.
417 The citations in these references were obtained in order to reconstruct the outbreak in detail and to
418 identify the most probable index case. Index cases were defined as any human infection resulting
419 from interaction with non-human sources of the disease. Some of these cases arose from presumed
420 interactions with zoonotic reservoirs or hosts, such as primates and other mammals during hunting
421 trips (*Boumandouki et al., 2005; Nkoghe et al., 2005; Nkoghe et al., 2011; WHO, 2003*) or butchering
422 of bats (*Leroy et al., 2009*). Any cases arising from existing human infections are considered as
423 secondary infections rather than index cases. Similar to methodology employed elsewhere (*Messina et*
424 *al., 2014*), the site, or supposed site, of this zoonotic transmission event was geopositioned using
425 Google Earth. For locations where precise geographic information (*e.g.* geographic coordinates of a
426 hunting camp) was provided by the authors, these were used. Where precise geographic information
427 could not be accurately geopositioned, a geographic area (termed a polygon) was defined covering the
428 reported region. In several cases only the first reported patient could be identified, with the source of

429 infection unknown. With these outbreaks the location of the first patient was geopositioned under the
430 assumption that an initial zoonotic spillover event occurred in the vicinity of this location. In two
431 outbreaks multiple independent zoonotic transmission events were identified (*Nkoghe et al., 2005*;
432 *Pourrut et al., 2005*; *WHO, 2003*), and each unique event was geopositioned and included in the
433 model as separate entities. Table 1 catalogues the outbreaks used in this study.

434 Assembling a database of reported infections in animals

435 A literature search was conducted in Web of Science using the search term “Ebola” that returned
436 8,635 citations. The abstracts were examined and for those that contained possible data on animal
437 Ebola infection, the full text was obtained. The sampling site or location of the animal in the study
438 was identified and geopositioned using Google Maps. These locations were recorded either as precise
439 locations or as polygons, as with human index cases. Records for which local transmission of Ebola
440 virus was deemed unlikely (*e.g.* seropositive primates tested in containment facilities several years
441 after their capture) were excluded from the study. The non-human Ebola virus occurrence data
442 collected are detailed in Table 2, including the diagnostic methods used.

443 GenBank isolates

444 The open access sequence database GenBank (*NCBI, 2014*) was searched using MESH Umbrella
445 search terms for Ebola virus, returning 181 results. These were then manually cross-referenced with
446 the existing human and animal Ebola information, collected above, and 30 duplicates were removed.
447 For the remaining isolates, original references and GenBank information fields were examined, but as
448 there was insufficient information to establish precise location of isolation and/or whether the isolate
449 represented an index case for any of these data sources, they were excluded from subsequent analyses.

450 Covariates assembled and used in the analyses

451 A suite of ecologically relevant gridded environmental covariates for Africa was compiled, each
452 having a nominal resolution of 5km x 5km. The environmental covariates used in this analysis were:
453 elevation (from the shuttle radar topography mission (*ORNL DAAC, 2000*)); the mean value, and a
454 measure of spatial variation (range, described below) between 2000 and 2012 of Enhanced Vegetation
455 Index (EVI), daytime Land Surface Temperature (LST) and night-time LST; and mean potential
456 evapotranspiration from 1950-2000 (*Trabucco and Zomer, 2009*) (Figure 5 – figure supplement 1).

457 The EVI and LST datasets were derived from satellite imagery collected by NASA’s Moderate
458 Resolution Imaging Spectroradiometer (MODIS) remote sensing platform (*Tatem et al., 2004*). EVI is
459 a metric designed to characterise vegetation density and vigour based on the ratio of absorbed
460 photosynthetically active radiation to near infrared radiation (*Huete et al., 2002*). LST is a modelled
461 product derived from emissivity as measured by the MODIS thermal sensor (*Wan and Li, 1997*),

462 which is correlated, though not synonymous with air temperature, and effective for differentiating
463 landscapes based on a combination of thermal energy and properties of surface types. The MODIS
464 datasets utilized in this research (EVI was derived from the MCD43B4 product and the MOD11A2
465 LST product was used directly) were acquired as composite datasets created using imagery collected
466 over multiple days, a procedure that results in products with eight-day temporal resolutions. Despite
467 compositing, the EVI and LST datasets contained gaps due to persistent cloud cover found in forested
468 equatorial regions, and these gaps were filled using a previously described approach (*Weiss et al.,*
469 *2014*). The EVI and LST datasets were then aggregated from their native 1km x 1km spatial
470 resolution to a final 5km x 5km resolution, calculating both the mean and the range of the values of
471 the subpixels making up each larger pixel. These spatial summaries therefore characterise both the
472 mean temperature in each location as well as the degree of spatial heterogeneity within that pixel. This
473 is of interest as humans and susceptible species are more likely to come into contact in transitional
474 areas (*e.g.* boundary areas between areas of highly suitable susceptible species habitat and areas
475 heavily utilised by humans). The final covariate production step consisted of summarising temporally
476 across the 13-year data archive to produce synoptic datasets devoid of annual or seasonal anomalies
477 (*Weiss et al., 2014*).

478 Implicated bat reservoir distributions

479 Over recent years, significant research has been undertaken in investigating the role bats have to play
480 in the transmission cycle of Ebola viruses (*Olival and Hayman, 2014*) and evidence of asymptomatic
481 infection in fruit bats has been documented to varying extents (*Hayman et al., 2010; Hayman et al.,*
482 *2012; Leroy et al., 2005; Pourrut et al., 2007; Pourrut et al., 2009*). In order to incorporate this
483 potential driver of Ebola virus transmission into the model we developed predicted distribution maps
484 for three species of fruit bat implicated as primary reservoirs of the disease: *Hypsignathus monstrosus*,
485 *Epomops franqueti* and *Myonycteris torquata*. The evidence was strongest for these three species
486 having a reservoir role as Ebola virus RNA (all nested within the *Zaire ebolavirus* phylogeny (*Leroy*
487 *et al., 2005*)) has been detected in all three. Whilst a handful of other bat species have been found to
488 be seropositive, no further viral isolations have been recorded (*Olival and Hayman, 2014*).

489 Whilst expert opinion range maps for these species exist (*Schipper et al., 2008*), there is some
490 disagreement with independently-sourced occurrence data (all archived in the Global Biodiversity
491 Information Facility). As a result, a predictive modelling approach was used to create a continuous
492 surface of habitat suitability for these species which we then included as a predictor in the model.
493 Occurrence data for all Megachiroptera in Africa was extracted from GBIF (*GBIF, 2014*) using the R
494 packages *dismo* (*Hijmans et al., 2014*) and *taxize* (*Chamberlain et al., 2014*). To remove apparently
495 erroneous records in the GBIF archive all occurrence records more than 100km from the species
496 known ranges, as determined by expert-opinion range maps (*Schipper et al., 2008*), were excluded, as

497 were duplicate records and those located in the ocean. This resulted in a total dataset of 1341 unique
498 occurrence records.

499 The occurrence database was then used to train separate boosted regression tree species distribution
500 models (*Elith et al., 2008*) to predict the likely distribution of each of these suspected reservoir
501 species. For each model, occurrence records for the target species (*H. monstrosus*, n=67; *E. franqueti*,
502 n=120; and *M. torquata*, n=52) were considered presence records and occurrence records of all other
503 species were used as background records. This procedure is designed to account for the potentially
504 biasing effect of spatial variation in recording of Megachiroptera occurrences (*Phillips et al., 2009*).

505 For each species we ran fifty submodels each trained to a randomly selected bootstrap of this dataset,
506 subject to the constraint that each bootstrap contained a minimum of ten occurrence and ten
507 background records. Each submodel was fitted using the `gbm.step` subroutine (*Elith et al., 2008*) in
508 the `dismo` R package. In each submodel the background records were down weighted so that the
509 weighted sum of presence records equalled the weighted sum of background records (*Barbet-Massin*
510 *et al., 2012*) in order to maximise the discrimination capacity of the model. We generated a prediction
511 map from each of these submodels and calculated both the mean prediction and 95% confidence
512 interval around the prediction for each 5km x 5km pixel for each species.

513 Model accuracy was assessed by calculating the mean area under the curve (AUC) statistic for each
514 submodel under a stringent ten-fold cross validation for each submodel and obtaining the mean and
515 standard deviation across all fifty submodels. Under this procedure the dataset was split into ten
516 subsets, each containing approximately equal numbers of presence and background points. The ability
517 of a model trained on each subset to predict the distribution of the other 90% of records was assessed
518 by AUC and the mean value taken. As so few presence records were used to train each fold model
519 (*i.e.* around five presence records for *M. torquata* up to twelve for *E. franqueti*), this represents a very
520 stringent test of the model's predictive capacity. Additionally, to prevent inflation of the accuracy
521 statistics due to spatial sorting bias, these statistics were estimated using a pairwise distance sampling
522 procedure (*Hijmans, 2012*). Consequently, the AUC statistics presented here are lower than would be
523 returned by standard procedures but gives a more realistic quantification of the model's ability to
524 extrapolate predictions to new regions (*Wenger and Olden, 2012*). We also generated marginal effect
525 plots with associated uncertainty intervals and relative contribution statistics (how often each
526 covariate was selected during the model fitting process) as quantification of the sensitivity of the
527 model to the different covariates. These allow us to make inferences about the ecological relationship
528 between each species and its environment as well as to identify where this relationship is most
529 uncertain.

530 To generate a single surface describing the distribution of the bat reservoir species to be used as a
531 covariate in the subsequent Ebola modelling, the three mean prediction distribution maps were
532 merged by taking the average habitat suitability for each of the three bat species at each pixel.

533 Ebola distribution modelling

534 The Ebola virus occurrence dataset was supplemented with a background record dataset generated by
535 randomly sampling 10,000 locations across Africa, biased towards more populous areas as a proxy for
536 reporting bias (*Phillips et al., 2009*). We fitted 500 submodels to bootstraps of this dataset. To account
537 for uncertainty in the geographic location of those occurrences reported as polygons, for each
538 submodel one point was randomly selected from each of these occurrence polygons. This Monte
539 Carlo procedure enabled the model to efficiently integrate over the environmental uncertainty
540 associated with imprecise geographic data. A bootstrap sample was then taken from each of these
541 datasets and used to train the BRT model using the same procedure and weighting of background
542 records as for the bat distribution models. Similarly, we generated a prediction map from each of
543 these models and calculated both the mean prediction and corresponding 95% confidence intervals for
544 each pixel and analysed prediction accuracy using the same stringent cross validation and sensitivity
545 analysis procedure as for the bat distribution models (detailed above).

546 The predicted distribution map produced by this approach represents the environmental suitability of
547 each pixel for zoonotic Ebola virus transmission. This may be interpreted as a relative probability of
548 presence in the sense that more suitable pixels are more likely to contain zoonotic transmission than
549 less suitable pixels, though not an absolute probability that transmission occurs in a given pixel.
550 Similarly, the presence of zoonotic transmission increases the risk of transmission to a human, though
551 this is also contingent on how humans interact with these zoonotic pools, through hunting or other
552 activities.

553 Population living in areas of environmental suitability for zoonotic transmission.

554 In order to identify areas which are likely to be at risk of transmission of *Ebolavirus* from zoonotic
555 reservoir hosts to humans, the continuous map of the predicted environmental suitability for zoonotic
556 transmission (shown in Figure 5) was converted into a binary map classifying pixels as either at risk
557 or not at risk. A pixel was assumed to be at risk if its predicted environmental suitability for zoonotic
558 Ebola virus transmission was greater than 0.673, the lowest suitability value predicted at the locations
559 of known transmission to humans (point records of human index cases). Countries containing at least
560 one at-risk pixel are shown in Figure 5B – those countries that previously report an index case were
561 defined as Set 1; countries with at least one at-risk pixel with no previous index cases of EVD were
562 categorised as Set 2. The number of people living in at-risk areas in each of these countries was
563 calculated by summing the estimated population of at-risk pixels using population density maps from

564 the AfriPop project (*Linard et al., 2012; WorldPop, 2014*) and the proportion of those living in urban,
565 periurban and rural areas was evaluated using the Global Rural Urban Mapping Project
566 (*CIESIN/IFPRI/WB/CIAT, 2007*).

567 The R code used for all of the analysis has been made available on an open source basis
568 (https://github.com/SEEG-Oxford/ebola_zoonotic).

569 National level demographic and mobility data

570 For three separate years (1976, 2000 and 2014), total national populations were retrieved and the
571 proportion of rural to urban populations noted from World Bank statistics (*World Bank, 2014*). To
572 describe global air travel patterns from Set 1 and Set 2 countries, flight schedules data from the
573 Official Airline Guide, reflecting an estimated 95% of all commercial flights worldwide, were
574 analysed between 2000 and 2013 to calculate the annual volume of seats on direct flights that depart
575 from each predicted country and which have an international destination. Complementing these seat
576 capacity data, worldwide data on anonymised, individual passenger flight itineraries from the
577 International Air Transport Association (2012) (*IATA, 2014*) were analysed between 2005 and 2012 to
578 calculate the annual volume of international passenger departures out of each Set 1 and Set 2 country.
579 The IATA dataset represents an estimated 93% of the world's commercial air traffic at the passenger
580 level and includes points of departure and arrival and final destination information for travellers as
581 well as their connecting flights.

582 **Acknowledgments**

583 We thank Katherine Battle, Maria Devine and Kirsten Duda for proof-reading and Jane Messina for
584 creating Figure 1. We also thank Andrew Rambaut for his comments on the final draft.

585

586 **Author contributions**

587 DMP – advised and assembled the outbreak and animal infection data and wrote the manuscript

588 NG – extracted the bat data and conducted all of the analysis

589 AM – assembled and geo-positioned the outbreak and animal infection data

590 ZH – geo-positioned the outbreak and animal infection data and provided all maps

591 AJH – analysed international flight data and helped assemble maps

592 DJW – assembled the covariate layers

593 OJB – screened GenBank data, provided Figure 2A and edited drafts of the manuscript

594 MUGK – edited drafts of the manuscript

595 DLS – edited drafts of the manuscript

596 CLM – edited drafts of the manuscript

597 SB – extracted Ebola information from GenBank

598 PWG – assembled the covariate layers

599 PWH – advised on international public health context and edited the final draft

600 IIB – assisted with international transportation analysis and edited the final draft

601 JSB – advised on international public health context and edited the final draft

602 SRM – assisted in geopositioning and contributed to the manuscript

603 AJT – provided information on urban change and migration data

604 KK – provided data and conducted all analyses on international air traffic patterns

605 SIH – conceived the work and analysis, wrote content and edited the manuscript at all stages of
606 development. He acts as guarantor of the paper.

607 **Funding**

608 DMP is funded by a Sir Richard Southwood Graduate Scholarship from the Department of Zoology at
609 the University of Oxford. NG is funded by a grant from the Bill & Melinda Gates Foundation
610 (#OPP1053338). ZH and AH are funded by the Bill & Melinda Gates Foundation (#OPP1106023).
611 OJB is funded by a BBSRC studentship. PWG is a Medical Research Council (UK) Career
612 Development Fellow (#K00669X) and receives support from the Bill & Melinda Gates Foundation
613 (#OPP1068048) which also supports DJW and SB. MUGK is funded by the German Academic
614 Exchange Service (DAAD) through a graduate scholarship. JSB and SRM acknowledge funding from
615 NIH National Library of Medicine (R01LM010812) and from the Bill & Melinda Gates Foundation
616 (#OPP1093011). AJT is supported by funding from NIH/NIAD (U19AI089674) and the Bill &
617 Melinda Gates Foundation (#OPP1106427, #OPP1032350). PWH is funded by the EU FP7 project
618 PREPARE (#602525) and the Li Ka Shing Foundation. KK and IIB acknowledge the support of the
619 Canadian Institutes of Health Research. SIH is funded by a Senior Research Fellowship from the
620 Wellcome Trust (#095066) which also supports AM and a grant from the Bill & Melinda Gates
621 Foundation (#OPP1093011) which also supports CLM. SIH and AJT would also like to acknowledge
622 funding support from the RAPIDD program of the Science & Technology Directorate, Department of
623 Homeland Security, and the Fogarty International Center, National Institutes of Health. Funders had
624 no role in study design, data collection and analysis, decision to publish, or preparation of the
625 manuscript.

1037 **Figure 1 – The epidemiology of Ebola virus transmission in Africa.** Of the suspected reservoir
1038 species, 1, 2 and 3 represent the three bat species from which Ebola virus has been isolated
1039 (*Hypsignathus monstrosus*, *Myonycteris torquata* and *Epomops franqueti*) and *n* represents unknown
1040 reservoirs of the disease yet to be discovered. Of the susceptible species, *A* represents *Pan*
1041 *troglodytes*, *B* *Gorilla gorilla* and *m* represents other organisms susceptible to the disease, such as
1042 duikers. *H* represents humans. Blue arrows indicate unknown transmission cycles or infection routes
1043 and red arrow routes have been confirmed or are suspected. Adapted from *Groseth et al. (2007)*.

1044 **Figure 2 –The locations of Ebola virus disease outbreaks in humans in Africa.** Panel A illustrates
1045 the 23 reported outbreaks of Ebola virus disease through time, with the area of each circle and its
1046 position along the y-axis representing the number of cases. The onset year is represented by the colour
1047 as per Panel B. Panel B shows a map of the index cases for each of these outbreaks. Panels C through
1048 H show these outbreaks over a series of time periods. Numbers refer to outbreaks as listed in Table 1.
1049 In panels B-H the species of *Ebolavirus* responsible for the outbreak is illustrated by the symbol
1050 shape, the number of resulting cases and onset date by symbol colour. The most recent outbreak (#23)
1051 is indicated in orange. Countries in which zoonotic transmission to humans has been reported or is
1052 assumed to have occurred are coloured in blue. In each map the Democratic Republic of Congo is
1053 outlined for reference.

1054 **Figure 3 –The locations of reported Ebola virus infection in animals in Africa.** Panel A shows the
1055 locations of reported Ebola virus infection in animals. Panels B through D show these records in
1056 animals over three different time periods. Numbers refer to records as listed in Table 2. In all panels,
1057 the species in which infection was detected is given by symbol shape and the year recorded by symbol
1058 colour. Blue countries represent locations where zoonotic transmission to humans has been reported
1059 or is assumed to have occurred. In each map the Democratic Republic of Congo is outlined for
1060 reference.

1061 **Figure 4 – Predicted geographical distribution of the three species of Megachiroptera suspected**
1062 **to reservoir Ebola virus.** Panel A shows the distribution of the hammer-headed bat (*Hypsignathus*
1063 *monstrosus*), panel B the little collared fruit bat (*Myonycteris torquata*) and panel C Franquet's
1064 epauletted fruit bat (*Epomops franqueti*). In each map, the locations of reported observations of each
1065 species, extracted and curated from the Global Biodiversity Information Facility (*GBIF, 2014*) and
1066 used to train each model are given as grey points (*H. monstrosus*, n=67; *E. franqueti*, n=120 and *M.*
1067 *torquata*, n=52). Expert opinion maps of the known range of each species, generated by the IUCN
1068 (*Schipper et al., 2008*), are outlined in grey. The colour legend represents a scale of the relative
1069 probability that the species occurs in that location from 0 (white, low) to 1 (green, high). Area under
1070 the curve statistics, calculated under a stringent ten-fold cross validation procedure, are 0.63±0.04,

1071 0.59±0.04 and 0.58±0.03 for *H. monstrosus*, *M. torquata* and *E. franqueti* respectively. Panel D is a
1072 composite distribution map giving the mean, relative probability of occurrence from panels A-C.

1073 **Figure 5 – Predicted geographical distribution of the zoonotic niche for Ebola virus.** Panel A
1074 shows the total populations living in areas of risk of zoonotic transmission for each at-risk country.
1075 The grey rectangle highlights countries in which index cases of Ebola virus disease have been
1076 reported (Set 1); the remainder are countries in which risk of zoonotic transmission is predicted, but in
1077 which index cases of Ebola have not been reported (Set 2). These countries are ranked by population
1078 at risk within each set. The population at risk figure in 100,000s is given above each bar. Panel B
1079 shows the predicted distribution of zoonotic Ebola virus. The scale reflects the relative probability that
1080 zoonotic transmission of Ebola virus could occur at these locations; areas closer to 1 (red) are more
1081 likely to harbour zoonotic transmission than those closer to 0 (blue). Countries with borders outlined
1082 are those which are predicted to contain at-risk areas for zoonotic transmission based on a
1083 thresholding approach (see Methods). The area under the curve statistic, calculated under a stringent
1084 ten-fold cross-validation procedure is 0.85±0.04. Solid lines represent Set 1 whilst dashed lines
1085 delimit Set 2. Areas covered by major lakes have been masked white.

1086 **Figure 5 – figure supplement 1 – Covariates used in predicting zoonotic transmission niche of**
1087 **Ebola.** Panel A displays elevation across Africa measured in metres, relative to sea level. Panels B
1088 and C show enhanced vegetation index (EVI) values (mean and spatial range respectively) on a scale
1089 from 0 to 1. Panels D through G display land surface temperature (LST) (mean and spatial range for
1090 day and night respectively) measured in degrees Celsius. Panel H shows potential evapotranspiration
1091 (PET) for Africa, in millimetres per month and Panel I gives the composite, relative probability of
1092 occurrence of the three suspected reservoir bat species. For details of how each of these covariate
1093 layers was derived see Methods.

1094 **Figure 5 – figure supplement 2 – Marginal effect plots for each covariate used in the Ebola virus**
1095 **distribution model.** Each panel illustrates the marginal effect (averaging over the effects of other
1096 covariates) that changes in each of the covariates has on the predicted relative probability of
1097 occurrence of zoonotic Ebola virus transmission. Grey regions and solid lines give the 95%
1098 confidence region (a metric of uncertainty) and mean value calculated across all 500 submodels. The
1099 mean relative contribution of the covariate to the model (the proportion of iterations in which the
1100 covariate was selected by the model-fitting algorithm, indicating sensitivity to the covariates) is given
1101 as an inset number. The dependency plots are ordered by mean relative contribution of the covariate.
1102 EVI = enhanced vegetation index, LST = land surface temperature and PET = potential
1103 evapotranspiration.

1104 **Figure 5 – figure supplement 3 – Comparison of predictions for zoonotic niche of Ebola virus**
1105 **excluding the Guinea outbreak.** Panel A shows the predicted zoonotic niche excluding the index

1106 case for the Guinea outbreak from the dataset used to train the model. Panel B shows the prediction
1107 when including the Guinea data in the model (the model presented in Figure 5). The circle depicts the
1108 location of the Guinean index case (#23 in Table 1). As per Figure 5, the scale reflects the relative
1109 probability that zoonotic transmission of Ebola virus could occur at these locations; areas closer to 1
1110 (red) are more likely to harbour zoonotic transmission than those closer to 0 (blue).

1111 **Figure 6 – Changes in national population for countries predicted to contain areas at-risk of**
1112 **zoonotic Ebola virus transmission.** For each country the population (in millions) is presented for
1113 three time periods (1976, 2000 and 2014) as three bars. Each stacked bar gives the rural (green) and
1114 urban (blue) populations of the country. The grey rectangle highlights countries in which index cases
1115 of Ebola virus diseases have been reported (Set 1); the remainder are countries in which risk of
1116 zoonotic transmission is predicted, but where index cases have not been reported (Set 2). The
1117 fractional change in population between 1976 and 2014 is given above each set of bars.

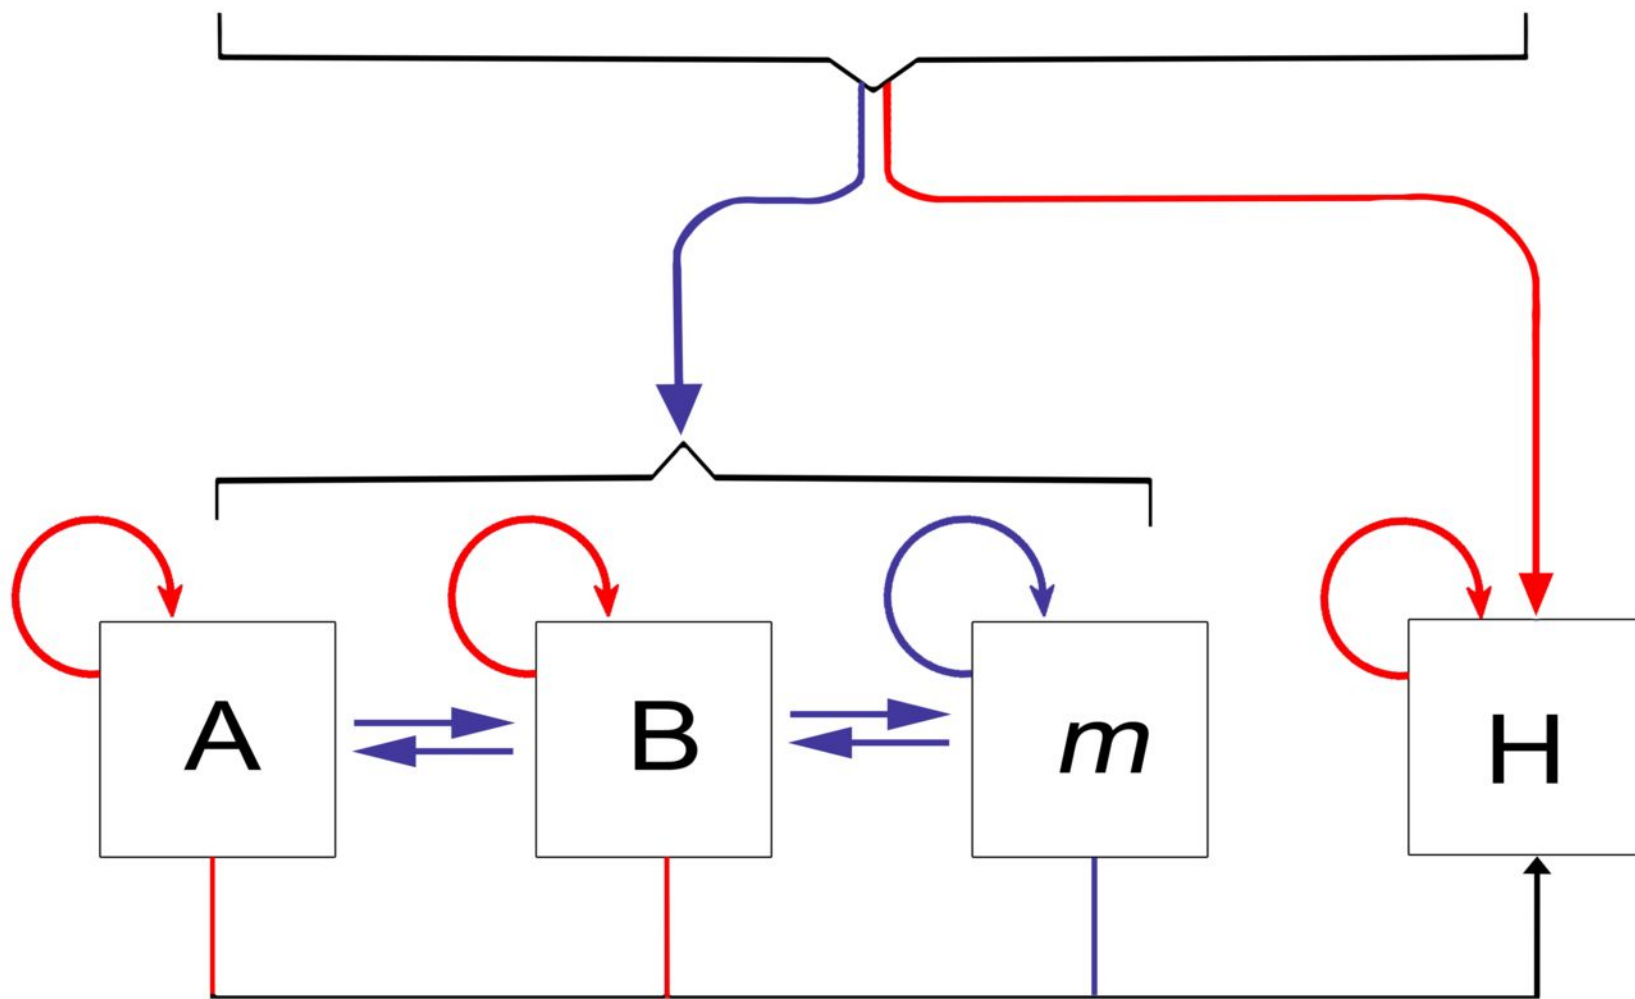

1118 **Figure 7 – Changes in international flight capacity and traveller volumes for countries predicted**
1119 **to contain areas at-risk of zoonotic Ebola virus transmission.** The grey rectangle highlights
1120 countries in which index cases of EVD have been reported (Set 1). The remainder are countries in
1121 which risk of zoonotic transmission is predicted, but where index cases have not been reported (Set
1122 2). Panel A shows changes in annual outbound international seat capacity (between 2000 in red and
1123 2013 in blue). Panel B depicts changes in annual outbound international passenger volume by country
1124 (between 2005 in red and 2012 in blue). For each country, the fractional change in volume is given
1125 above each set of bars. Note that only one bar is presented for South Sudan as data for this region
1126 prior to formation of the country in 2011 were unavailable]

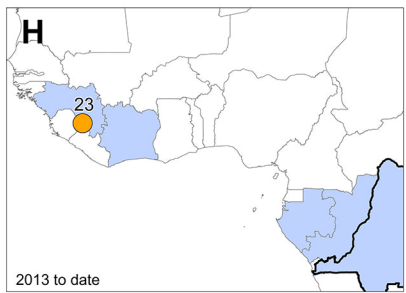

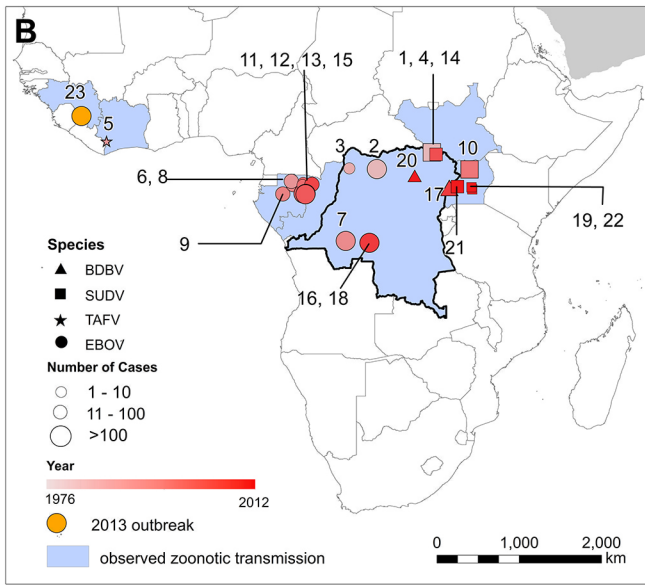

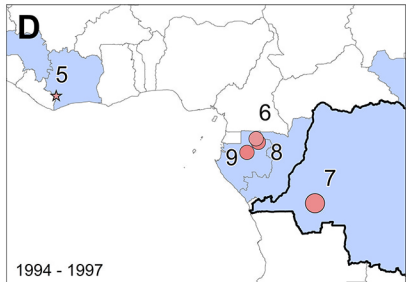

1127 **Figure 8 – Numbers of airline passengers arriving from at-risk countries to other countries**
1128 **stratified by major geographic regions and national income groups.** Panel A shows the locations
1129 of WHO regions (AFRO - African Region; AMRO – Region of the Americas; EMRO - Eastern
1130 Mediterranean Region; EURO - European Region; SEARO – South-East Asian Region; WPRO -
1131 Western Pacific Region). Panel B displays the numbers of passengers arriving in each of these regions
1132 from countries predicted to contain areas at risk of zoonotic Ebola virus transmission (Sets 1 and 2) in
1133 2005 and 2012. Panel C shows the income tiers of all countries as defined by the World Bank. Panel
1134 D displays the total numbers of passengers arriving in countries in each of these income strata from
1135 at-risk countries in 2005 and 2012. The number above each pair of bars indicates the fractional change
1136 in these numbers of incoming passengers between 2005 and 2012.
